Electrochemical Investigations of Li$_2$Fe$_{0.8-x}$Mn$_{0.2}$Si$_O_4$ (M = Mg$^{2+}$, Zn$^{2+}$) Cathodes for Lithium Ion Batteries

Shu-Dan Li, Yun Zhao, Chen-Yi Wang and Kun Gao*

School of Chemistry and Materials Science, Shanxi Normal University, 041004 Linfen, China

The Mn$^{2+}$ and Mg$^{2+}$ (or Zn$^{2+}$) co-doped Li$_2$Fe$_{0.8-x}$Mn$_{0.2}$Si$_O_4$ (x = 0.05 and 0.1) are synthesized by a solid-state reaction route. Compared with the single doped Li$_2$Fe$_{0.8}$Mn$_{0.2}$Si$_O_4$, the co-doped samples show improved cycling performance. The capacity retention can stay above 50% after 50 cycles, which is significantly higher than 30.4% for Li$_2$Fe$_{0.8}$Mn$_{0.2}$Si$_O_4$. This phenomenon could be attributed to the increased structural stability caused by the incorporation of the electrochemically inactive Mn$^{2+}$ ions. However, except for Li$_2$Fe$_{0.8}$Mn$_{0.2}$Zn$_{0.1}$Si$_O_4$, the other samples show decreased capacities, especially in the case of the Mn/Zn co-doping. Further tests indicate that the promotion of Li$^+$ diffusivity may be a key reason for the improved rate and cycling performances. By contrast, the incorporation of Zn$^{2+}$ impaired the cell performances such as increased internal polarization, hindered charge transfer, decreased Li$^+$ diffusivity. In this work, the Mg$^{2+}$ with smaller radius seems to be a better choice as the co-doping element at Fe sites than Zn$^{2+}$.

Keywords: chemically modified electrode, lithium battery, applied electrochemistry, composite and nanocomposite materials

Introduction

Compared with the other cathodes from the silicate family, Li$_2$FeSiO$_4$ has its own characteristics, such as: structural rearrangement, stable interface film, thermal regeneration. However, low electronic conductivity and slow lithium-ion diffusion are the biggest obstacles for the commercial application of Li$_2$FeSiO$_4$. To date, numerous approaches have been investigated to circumvent these main issues by improving the intrinsic and extrinsic properties of bulk Li$_2$FeSiO$_4$, e.g., cation doping, carbon coating and optimized preparation technology, etc. Some nano-Li$_2$FeSiO$_4$/C composites with novel shapes, such as Li$_2$FeSiO$_4$/C/CNS, hierarchical shuttle-like Li$_2$FeSiO$_4$/C, rod like Li$_2$FeSiO$_4$, and nano-spherical Li$_2$FeSiO$_4$/C, can approach or even exceed the theoretical capacity of 166 mAh g$^{-1}$. Especially, the Li$_2$FeSiO$_4$/C/MWCNTs (MWCNTs: multi walled carbon nanotubes) composites reported by Peng et al. had a high discharge capacity of 206.8 mA h g$^{-1}$ in the second cycle at 0.1 C, even at 20 C, the electrode could maintain 82 mA h g$^{-1}$ after 500 cycles. Moreover, the porous Li$_2$FeSiO$_4$/C nano-composites prepared by a simple P123 (EO$_{20}$PO$_{30}$EO$_{20}$) assisted sol-gel method, also delivered a first discharge capacity of 230 mAh g$^{-1}$ at 0.1 C corresponding to 1.39 mol Li$^+$ inserted per molecular formula. These works indicate that Li$_2$FeSiO$_4$ has a lot of potential as a promising cathode material for Li-ion battery.

In the past few years, cation doping was considered as one of the most effective methods to improve electronic conductivity and ion mobility. Various doping elements have been tried to improve the performance of Li$_2$FeSiO$_4$ materials. For example, Zhang et al. studied the impact of different doping elements including Mg$^{2+}$, Zn$^{2+}$/Cu$^{2+}$/Ni$^{2+}$, Cr$^{3+}$, on the electrochemical performance of Li$_2$FeSiO$_4$, and some improved results were observed. Among the related reports, Mn$^{2+}$ doping is of special concern, because Mn$^{2+}$ ion can solve into the crystal structure of Li$_2$FeSiO$_4$, and make up for the intrinsic disadvantage of low theoretical capacity (166 mAh g$^{-1}$). For example, Shao et al. prepared carbon-coated nanostructured Li$_2$Fe$_{0.8}$Mn$_{0.2}$Si$_O_4$ via a combination of spray pyrolysis and wet ball milling method, which displayed a discharge capacity as high as 149 mAh g$^{-1}$. Different from the above optimum Fe/Mn ratio, Guo et al. pointed out that Li$_2$Fe$_{0.5}$Mn$_{0.5}$Si$_O_4$/C synthesized by mechanical activation-solid-state reaction had a distinguished discharge capacity of 158.1 mAh g$^{-1}$ in the first cycle. Deng et al. also reported that the Li$_2$Fe$_{0.5}$Mn$_{0.5}$Si$_O_4$ prepared via citric acid assisted sol-gel method showed an initial discharge capacity above...
170 mAh g$^{-1}$. Especially, Li$_2$Fe$_{0.75}$Mn$_{0.25}$SiO$_4$/C reported by Wang and co-workers$^{13}$ using a modified sol-gel methods, inserted more than 1.0 mol Li$^+$ per molecular formula, and showed an initial discharge capacity of 201 mAh g$^{-1}$. However, all the Mn-doped samples presented worse cycling performance than pristine materials. About this, Bini et al.$^{14}$ pointed out that a significant cation disorder could top up to 80%, based on the Li/Fe(Mn) anti-site defect, which should seriously influence the structural stability of Li$_2$Fe$_{1-x}$Mn$_x$SiO$_4$/C composites. Moreover, Chen et al.$^{15}$ also found out that the amorphization and structural rearrangements of Li$_2$Fe$_{1-x}$Mn$_x$SiO$_4$ during the initial cycle and the redox processes of Mn species could be only involved in the first few cycles. Therefore, the structural stability and the efficiency of Mn species are the main problem facing the current ferromanganese lithium silicate materials.

Recently, the introduction of a second dopant has been proposed and widely studied in order to improve the electrochemical response of cathode material. Hu et al.$^{16}$ compared the properties of single doped LiMn$_{0.8}$Fe$_{0.2}$PO$_4$ and co-doped LiMn$_{0.8}$Fe$_{0.5}$Mg$_{0.2}$PO$_4$, and found that the LiMn$_{0.8}$Fe$_{0.5}$Mg$_{0.2}$PO$_4$ sample has much higher reversible capacity and rate capability as compared to LiMn$_{0.8}$Fe$_{0.2}$PO$_4$. Cui et al.$^{16}$ synthesized zinc- and PO$_4$-doped LiMn$_x$O$_4$ via traditional solid state reaction. The discharge capacity and cycling performance of the co-doped LiZn$_{0.05}$Mn$_{1.95}$O$_{3.99}$PO$_{0.025}$ were found to be superior to single doped LiZn$_{0.05}$Mn$_{1.95}$O$_{3.99}$.

With the expectation to improve the cycling capability of Li$_2$Fe$_{1-x}$Mn$_x$SiO$_4$ system, we choose common divalent cations (Mg$^{2+}$ and Zn$^{2+}$) combined with Mn$^{2+}$ as the co-doping elements at Fe sites and prepared Li$_2$Fe$_{1-x}$Mn$_x$M$_{1-x}$SiO$_4$ (M = Mg or Zn, x = 0.05, 0.1) cathodes by a solid state reaction. Their electrochemical properties were investigated and the possible synergistic mechanisms were discussed.

**Experimental**

The used metal salts: LiCH$_3$COO$\cdot$2H$_2$O, FeC$_6$O$_6$$\cdot$2H$_2$O, Mn(CH$_3$COO)$_2$$\cdot$4H$_2$O, ZnO and Mg(CH$_3$COO)$_2$$\cdot$4H$_2$O were purchased from Tianjin Guangfu Fine Chemical Research Institute, and nano-SiO$_2$ was provided from Henan Huanyu Power Source Co., Ltd. To prepare cathode materials, the stoichiometric amounts of SiO$_2$ and metal salts were first mixed together. To avoid the excessive impurities in the final products, only 5 wt.% mass of glucose (C$_6$H$_{12}$O$_6$$\cdot$H$_2$O) as carbon source was introduced to the above mixture, and the mixture were ground to fine powder together with an agate mortar and pestle. The resulting intimate mixtures were first dehydrated at 200 °C for 1 h, and then calcined at 700 °C for 10 h in a vacuum tube furnace keeping ~0.1 MPa vs. normal atmosphere. According to the ratio of metal salts in the initial precursor, the obtained final products with about 1.6 wt.% carbon (determined by high frequency infrared carbon-sulfur determination, CS 600, Germany Eltar), were named as Li$_2$Fe$_{1.8}$Mn$_{0.2}$SiO$_4$ or Li$_2$Fe$_{0.9}$Fe$_{0.1}$Mn$_{0.2}$SiO$_4$ (M = Mg or Zn).

The crystal structures were analyzed by powder X-ray diffraction (Ultima IV, Rigaku) employing Cu K$_\alpha$ radiation (λ = 0.154056 nm) in the two-theta range of 10-80°. The morphologies and chemical distributions were observed using a field-emission scanning electron microscope (FESEM, JSM-7500F, Japan JEOL) equipped with an energy dispersive X-ray analyzer (EDX, Oxford Inca PentaFET x3).

The mixture of Li$_2$Fe$_{1.8}$Mn$_{0.2}$M$_{0.8}$SiO$_4$ powder, acetylene black and polyvinylidene fluoride with a weight ratio of 80:10:10 was used as the cathode. The dry strip cathodes were cut into the disks (16 mm in diameter) containing 6-8 mg active materials. Then, the Li$_2$Fe$_{1.8}$Mn$_{0.2}$M$_{0.8}$SiO$_4$/Li coin cells were fabricated in an Ar-filled glove box. The cycling and rate performances were characterized on a 5 V per 2 mA battery testing system (Land 2005A, Wuhan Jinnuo Electronics Co., Ltd.) with cut-off voltage of 1.5-4.5 V vs. Li/Li at a constant current from 0.06 to 2 C. The electrochemical impedance spectra (EIS) of the cycled cells were obtained using an electrochemical workstation (CHI 604D, Shanghai CH Instruments, Inc.) in a range of 0.1-100 kHz at the amplitude of 5 mV. The cyclic voltammetry (CV) was also tested with CHI 604D at a scanning rate of 1.0 mV s$^{-1}$ at room temperature. Capacity intermittent titration technique (CITT) proposed by Tang et al.$^{18}$ was used to investigate the Li-ion diffusion coefficient (D$_{Li^+}$). The cell was first galvanostatically-charged (5 mA g$^{-1}$) to a certain cutoff voltage, then potentiostatically-charged at this cutoff voltage until the current tends to zero. Here, the set current is 0.05 mA g$^{-1}$. The whole charge voltage ranges (1.5-4.5 V) were divided into many small voltage regions and separated from one another by 0.1 V. When the charging was completed, the tested cell was discharged with 10 mA g$^{-1}$ current to 2.0 V. The above procedures were continuously repeated for five cycles.

**Results and Discussion**

Figure 1 compares the X-ray diffraction (XRD) patterns of the synthesized Li$_2$Fe$_{1.8}$Mn$_{0.2}$M$_{0.8}$SiO$_4$ samples. The Li$_2$Fe$_{1.8}$O$_4$ impurity can be easily detected, small Li$_2$SiO$_3$ also emerged in the Mn/Mg co-doped samples. The remaining diffraction peaks are very similar to each other,
indicating that small amounts of co-doping elements have not changed Li$_2$FeSiO$_4$ architecture. However, the broad peaks indicate that in neither case the crystallinity is good. The quality of XRD patterns does not allow a good Rietveld refinement, but the matching results of XRD patterns, especially in low angle region, suggest that the obtained samples should be a mixed phases of P2$_1$/n and Pmn$_2$ co-existence. Furthermore, the co-doping of Mg$^{2+}$ or Zn$^{2+}$ caused some observable variations in the diffraction peak positions. For example, the strongest diffraction peak around 33° gradually shifted toward higher 2θ values with the increase of Mg content from 0 to 0.1, which could be easily seen from the enlarged patterns located at the right side of Figure 1. Recently, Dimesso et al. reported the influence of different Mg-ion additions on the structure of the olivine-structured LiCo$_{1-x}$Mg$_x$PO$_4$. Their results showed a shift in the positions of the (311) and (121) reflections towards higher diffraction angles. By contrast, due to the similar radius of Zn$^{2+}$ (0.74 Å) and Fe$^{2+}$ (0.76 Å), the Mn/Zn co-doping did not cause changing in the position of the reflection at 33°/2θ, and a shoulder peak always well evident. The XRD results suggest that Mg$^{2+}$ and Zn$^{2+}$ have been successfully introduced into Li$_2$FeSiO$_4$ matrix structure. Moreover, the XRD patterns do not show any peak related to crystal carbon, which indicates the introduced carbon should be in amorphous form in the final samples.

However, based on the local view, the Mn/Zn co-doping seems to produce more serious agglomerates and less uniform particle size. The further EDX (energy dispersive X-ray) spot data in Table 1 show that the atomic ratio of Fe/Mn/Mg/Si/O in samples was very close to the designed ratio of the Li$_2$Fe$_{0.8}$Mn$_{0.2}$Mg$_x$SiO$_4$ formula. It demonstrates that the co-doped elements incorporate very well with Li$_2$Fe$_{0.8}$Mn$_{0.2}$Mg$_x$SiO$_4$ host materials.

Although Li$_2$FeSiO$_4$ capacity could be greatly improved by Mn$^{2+}$ doping, Li$_2$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$ has been demonstrated experimentally with the 30-40% capacity loss after 50 charge-discharge cycles in many reports. A similar observation can be seen in our experiments. As shown in Figure 3b, the Li$_2$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$/Li cell exhibited a serious capacity loss and only maintained about 30.4% of discharge capacity at 50th cycle (38.6 mAh g$^{-1}$), as compared to that at 1st cycle (127 mAh g$^{-1}$). Moreover, it is necessary to point out that the present Li$_2$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$ performance is lower than that in our previous report. This is because that smaller carbon was introduced in the present series experiments in order to avoid more impurities resulting from excessive carbon, and highlight the effect of co-doping.

Based on the charge-discharge data in Figure 3, we can summarize some key things as follow: (i) the initial charge curves of all samples are obviously higher than those in the subsequent cycles, which means that the single-doping of Mn$^{2+}$ or the further co-doping of Mg$^{2+}$ or Zn$^{2+}$ do not change the inherent characteristic of structural rearrangement of Li$_2$FeSiO$_4$ material; (ii) the initial dQ-dV curves in Figure 3a exhibit two clear voltage plateaus at about 3.5 and 4.4 V. After Mg$^{2+}$ or Zn$^{2+}$ co-doping, the area of oxidation peak located at about 3.5 V increases. At the same time, a shift of reduction peak located at about 2.5 V towards the right means less internal polarization. Novikova et al. also observed similar phenomenon that the slope of the voltage plateau for the co-doped samples is lower than that of single-doped sample, and they attribute it to the improved ionic conductivity; (iii) the initial discharge capacities of the co-doped samples are lower than that of 127 mAh g$^{-1}$ for the single-doped sample. For example, in the case of the Mn/Mg co-doped samples, when x is 0.05 and 0.1, the initial discharge capacities are 118 and 108.5 mAh g$^{-1}$, respectively. As for the Mn/Zn co-doped samples, lower discharge capacities of 96.8 and 79.6 mAh g$^{-1}$ are observed. This result can be interpreted as being due to the fact that the doped Mg$^{2+}$ or Zn$^{2+}$ in the crystal lattice cannot be oxidized to M$^{4+}$ or M$^{4+}$, they usually stay electrochemically inactive. The fact that the more M$^{2+}$ co-doping causes the lower discharge capacities is in agreement with the above inference. (iv) Cycling performances have been greatly improved by co-doping. For
example, Li$_2$Fe$_{0.8}$Mn$_{0.2}$Mg$_x$SiO$_4$ samples show the discharge capacities of 74.9 and 63.2 mAh g$^{-1}$ after 50 cycles, when $x$ is 0.05 and 0.1, and the corresponding capacity retentions are 63.5 and 58.2%, as compared to their initial discharge capacities, respectively. Similarly, capacity retention is 53.6 and 69.5% for Li$_2$Fe$_{0.8}$Mn$_{0.2}$Zn$_x$SiO$_4$ samples, in spite of their lower discharge capacities of 51.9 and 55.3 mAh g$^{-1}$ at 50th cycle. We think that the inactive M$^{2+}$ could have the buttressing effect on crystal lattice when Li-ions are extracted from host cathodes. Therefore, the co-doped materials have more resistance to amorphisation than Li$_2$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$. However, along this inference, Li$_2$Fe$_{0.8}$Mn$_{0.2}$Mg$_{0.1}$SiO$_4$ samples show the opposite result. The capacity retention of $x = 0.1$ is only 58.2%, less than 63.5% of $x = 0.05$. A similar phenomenon was explained by Huang et al. that the existence of too many doping ions in the crystal lattice may induce large changes to the structure and cause the phase instability. Among all samples, Li$_2$Fe$_{0.75}$Mn$_{0.2}$Mg$_{0.05}$SiO$_4$ shows the most excellent performance in charge-discharge capacity and cycling property.

Figure 2. SEM-EDX spot images of original magnification 10,000x of Li$_2$Fe$_{0.8}$Mn$_{0.2}$M$_x$SiO$_4$ (M = Mg and Zn, $x = 0.05$ and 0.1).
Due to low Li$^+$ diffusivity and poor electronic conductivity of silicate cathodes, Li$_2$MSiO$_4$ materials usually have a major drawback to their capacity performances, especially at high rates. As shown in Figure 4, all Li$_2$Fe$_{0.8-1.2}$Mn$_{0.2}$SiO$_4$/Li cells present poor rate performances in the current range from 0.25 to 2 C. Among these samples, only Li$_2$Fe$_{0.75}$Mn$_{0.25}$SiO$_4$/Li cell has an improved rate performance, whose discharge capacity is 78.1, 69.7, 58.2, 49.8, 40.7 and 35.6 mAh g$^{-1}$ at the current rates of 0.25, 0.375, 0.5, 0.75, 1.0, 2.0 C, respectively.
However, when Mg$^{2+}$ content increases to 0.1, the sample has a similar performance to that of Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$. By contrast, both the Mn/Zn co-doped samples presented worse rate performances, especially Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$Zn$_{0.1}$SiO$_4$ even does not work at 2.0 C.

Figure 5 depicts the CV curves of Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$/Li cells, conducted at a scan rate of 1.0 mV s$^{-1}$ to elucidate the redox chemistry in a better way. All the CV profiles are similar. A strong reduction peak with good repeatability appears at about 2.4 V in the cathodic scan, while the anodic scan exhibits two broad oxidation peaks, in which the lower voltage oxidation peak (LOP) at about 3.4 V can be attributed to the dominating Fe$^{3+}$/Fe$^{2+}$ redox process on cycling, it is located at a slightly higher potential (3.6-3.8 V) in the first cycle. In view of Wang et al.$^{15}$ the CV profiles of Li$_{1-x}$MnSiO$_4$/Li cells showed two oxidation peaks located at 4.4 and 4.8 V corresponding to the Mn$^{4+}$/Mn$^{3+}$ and Mn$^{4+}$/Mn$^{3+}$ redox couples during the initial charge, respectively. Then they moved obviously to the lower voltages in the subsequent cycles. Therefore, the higher voltage oxidation peak (HOP, > 4.2 V) in our experiment can be mainly associated with the Mn$^{4+}$/Mn$^{3+}$ redox couple except for the initial charge. Possibly, there may be a few Fe$^{3+}$/Fe$^{4+}$ reactions occurred at local crystal structure.

In the case of Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$, the oxidation peak (> 4.2 V) of the second scan is significantly lower than that of the first cycle, as shown in Figure 5a. This observation just matches up with the conclusion suggested by Chen et al.$^{15}$ that the redox processes of Mn species only can be involved in the first few charge-discharge cycles. As for the Mn/Mg co-doped samples (Figures 5b and 5c), we can notice three changes: (i) during the first lithium de-intercalation process, the Mn/Mg co-doped samples have lower first LOP than the other samples. When $x = 0.05$, LOP presents a significant peak at 3.3 V accompanied with a weak transition peak at 3.7 V. However, when $x = 0.1$, the LOP always stays at about 3.35 V. By contrast, the corresponding LOP locate at 3.75 V for Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$, 3.8 and 3.65 V for the Mn/Zn co-doped samples, respectively. This fact indicates that, the Mg-substituted system has a smaller inner polarization, which usually means an easier lithium de-intercalation from host cathode. Here, the lower HOP suggests that Mg$^{2+}$ doping could reduce the energy barrier for lithium migration; (ii) the intensity of HOP (> 4.2 V) only showed a slight decline with increasing cycles, suggesting that the incorporation of Mg$^{2+}$ may be better to improve the oxidation from Mn$^{4+}$ to Mn$^{3+}$; (iii) CV profiles of Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$Mg$_{0.1}$SiO$_4$ samples have a better reproducibility in the test range of 1$^{st}$-5$^{th}$ cycle, implying the better electrode stability. By contrast, the Mn/Zn co-doped samples have extremely similar CV characteristics to Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$ sample except for some slight differences in redox peak position and response current intensity. Notice that the HOP intensity (> 4.2 V) is smaller and decreases rapidly; this suggests that the incorporation of Zn$^{2+}$ could impair the oxidation from Mn$^{4+}$ to Mn$^{3+}$.

Then, we calculated the intervals between the oxidation peak and the reduction peak during the first five CV cycles, which have been compared in Figure 5f. Because the oxidation peaks of HOP (> 4.2 V) is incomplete, limited by the voltage upper limit of 4.5 V, all the data come from the oxidation peak around 3.4 V and the reduction peak around 2.4 V. Moreover, the mean peak separation were used in the 2nd-5th CV cycles, the single difference was used at the first CV when considering structural rearrangement. This indicates that the introduction of Mg$^{2+}$ can help to lessen the inner polarization during the initial structural rearrangement process. In the subsequent CV (2nd-5th), the single doped sample (Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$) presents the smallest value (0.7748 V), while the peak intervals after Mn$^{2+}$ co-doping have different growth. Especially, in either case, the Mn/Zn co-doped samples show noticeable increases in polarization. The fact that more Mn$^{2+}$ doping leads to the greater polarization suggests that the incorporation of electrochemically inactive Mn$^{2+}$ ions could impede the extraction of Li-ions at LOP to some extent.$^{29}$ This result seems to be contradictory with cycling performances, because smaller resistance usually means better cell performance. However, note that CV data only present the mean peak intervals of 2nd-5th scan, thus taking them as evidence to explain long-cycling performance seems to be insufficient. In addition, the absence of HOP (> 4.2 V) might also bring certain errors in CV results.

Figure 6 shows XRD patterns and EIS spectra of the cycled Li$_{1-x}$Fe$_{0.8}$Mn$_{0.2}$Mg$^{2+}$SiO$_4$ samples. In Figure 6a, all the XRD patterns are similar and appear no sharp peaks. This proved a transformation from crystal structure into...
amorphous phase occurred after 50 cycles. Different from prior CV results presented in the first few cycles, the co-doped samples did not show a long-life advantage in structural stability. The Nyquist plots shown in Figure 6b are composed of a semicircle at middle frequency and a slope line at low frequency. The sloped line is related to the Li$^+$ diffusion in the electrode material, and the semicircle is connected with the interfacial impedance ($R_i$) including charge-transfer impedance ($R_{ct}$) and solid electrolyte interphase impedance ($R_{SEI}$). The spectra can be fitted by the equivalent circuit in our previous work. The obtained $R_i$ values were 278 Ω for Li$_2$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$, 289 and 404 Ω for the Mg co-doped samples, 626 and 667 Ω for the Zn co-doped samples, respectively. This result indicates that

![Figure 5](image_url)

Figure 5. The first five CV profiles (a-e) and mean peak separation; (f) of Li$_2$Fe$_{0.8-x}$Mn$_{0.2}$M$_x$SiO$_4$/Li cells (M = Mg and Zn, x = 0, 0.05 and 0.1).
the co-doping lead to bigger $R_i$ values, especially for the incorporation of Zn$^{2+}$. Therefore, the above XRD and EIS results cannot give sufficient reasons for the improved performance of Li$_2$Fe$_{0.75}$Mn$_{0.2}$Mg$_{0.05}$SiO$_4$. To further reveal this issue, we carried out CITT measurements of Li$_2$Fe$_{0.8-x}$Mn$_{0.2}$MxSiO$_4$/Li cells. The CITT technique was used to determine $D_{Li^+}$ values. Figure 7 compares the obtained CITT curves with various stair-step shapes. It can be seen that the voltage increases gradually in galvano-charge step and the current decreases gradually in the potenti-charge step. According to the reports, the following equation can be derived from the spherical diffusion model.

$$q = \frac{Q_p}{Q_g} = \frac{r^2}{3D_{Li^+}t_G} \left[ \frac{1}{5} - 2 \sum_{j=1}^{a_j} \exp \left( -\frac{a_j^2D_{Li^+}t_G}{r^2} \right) \right]$$ (1)

where $q$ is the ratio of $Q_p$ and $Q_g$, $t_G$ is the galvano-charge time (s), $r$ is the mean crystallite size, $\alpha_j$ is constant. Therefore, the equation gives the analytical solution associating $q$ value with the $D_{Li^+}$. We can get the desired data from the CITT curves in Figure 7, and then select the equations fitted by linear least-square fits according to for different ranges of $q$ value to calculate $D_{Li^+}$ values.

The obtained $D_{Li^+}$ values are compared in Figure 8. It can be seen that the $D_{Li^+}$ values varied non-linearly with the charge voltage as a wavy shape, all the $D_{Li^+}$ values are almost in the same order of magnitude ($10^{-16}$). Although the curve shapes are similar, the $D_{Li^+}$ values of Li$_2$Fe$_{0.75}$Mn$_{0.2}$Mg$_{0.05}$SiO$_4$ in the first cycle are higher than that of Li$_2$Fe$_{0.8}$Mn$_{0.2}$SiO$_4$ sample, especially when the voltage is higher than 4.2 V. This superiority is still retained during the second charging, in spite of the reversed results in the range of 2.8-4.2 V. The higher $D_{Li^+}$ values mean better Li diffusivity, so it proves that the incorporation of Mg$^{2+}$ can promote the extraction/insertion of Li$^+$ in the corresponding range. Also, note that the most $D_{Li^+}$ values at the same voltage in the second charging are higher than that in the first charging. However, for the Li$_2$Fe$_{0.8}$Mn$_{0.2}$Mg$_{0.05}$SiO$_4$ sample, the obtained $D_{Li^+}$ data in the first and second cycle are comparable. Recently, Araujo et al. pointed out that the $D_{Li^+}$ values of Li$_2$FeSiO$_4$ at room temperature
was only about $10^{-20}$-$10^{-17}$ cm$^2$s$^{-1}$, less than other with cathode materials ($10^{-15}$-$10^{-7}$ cm$^2$s$^{-1}$), therefore the kinetics of diffusion performance need to be improved. In our experiment, the Mg$^{2+}$ co-doping showed some positive effects on Li$^+$ mobility, especially above 4.2 V range, this may be one reason for its improved cell performances. It is need to point out that, because this study only compares the $D_{Li^+}$ values of the first two charging, so the corresponding data might not reflect the real potential of electrodes for their long cycling.

**Figure 8.** The $D_{Li^+}$-voltage curves determined from CITT data.

**Conclusions**

In this study, Li$_2$Fe$_{0.8-x}$Mn$_{0.2}$M$_{x}$SiO$_4$ (M = Mg and Zn, x = 0, 0.05 and 0.1) show very distinct cell performances. Firstly, the incorporation of the electrochemically inactive M$^{2+}$ ions can serve to strengthen crystal structure and improve the cycling performance significantly. However, note that the capacities show a serious loss with cycling for the Mn/Zn co-doped samples. Secondly, the Mg$^{2+}$ co-doping can bring more benefits, such as the increased capacity (x = 0.05) and the improved rate performance.

Thirdly, the XRD and EIS results showed that co-doping leads to the enlarged interfacial resistance and amorphous crystal structure after 50 cycles, but the CV and CITI results suggest that the Mg$^{2+}$ co-doping should improve Li-ion diffusion behavior at least in the first several cycles, especially above 4.2 V range. In conclusion, by comparing the Mg$^{2+}$ and Zn$^{2+}$ co-doped samples, the Mg$^{2+}$ with smaller radius seems to be a better choice in this work. The study on the Fe-site co-doping of Li$_2$FeSiO$_4$ including more elements will be performed in the future.
